A NOTE ON DELTA HEDGING IN MARKETS WITH JUMPS

ALEKSANDAR MIJATOVIĆ AND MIKHAIL URUSOV

Abstract. Modelling stock prices via jump processes is common in financial markets. In practice, to hedge a contingent claim one typically uses the so-called delta-hedging strategy. This strategy stems from the Black–Merton–Scholes model where it perfectly replicates contingent claims. From the theoretical viewpoint, there is no reason for this to hold in models with jumps. However in practice the delta-hedging strategy is widely used and its potential shortcoming in models with jumps is disregarded since such models are typically incomplete and hence most contingent claims are non-attainable. In this note we investigate a complete model with jumps where the delta-hedging strategy is well-defined for regular payoff functions and is uniquely determined via the risk-neutral measure. In this setting we give examples of (admissible) delta-hedging strategies with bounded discounted value processes, which nevertheless fail to replicate the respective bounded contingent claims. This demonstrates that the deficiency of the delta-hedging strategy in the presence of jumps is not due to the incompleteness of the model but is inherent in the discontinuity of the trajectories.

1. Introduction

The universal success of the Black–Merton–Scholes model (BMS model) is in no small measure due to the fact that the risk of a European contingent claim can be neutralised using a replication strategy which, at any moment in time, is a function solely of the current value of the underlying security. This strategy is known as the delta-hedging strategy and is universally applied in the financial markets across pricing models.

It is well documented in the literature that modelling stock prices as geometric Brownian motions is inconsistent both with the statistical properties exhibited by real financial data (“excess kurtosis and skewness”) and with the option prices observed in the financial markets (“implied volatility smile and skew”), see e.g. Lai and Xing [22], Shiryaev [29, Ch. IV] for the former, and Gatheral [13], and Lipton [24] for the latter. A widely used class of models, designed to deal with some of these issues, is processes with jumps (see e.g. Cont and Tankov [4], Schoutens [27]). The question of how to reduce the outstanding risk of a contingent claim in such a model, which typically does not allow perfect replication, remains of central importance for market practitioners. Even

Key words and phrases. Delta hedging, exact replication, martingale representation, Black–Merton–Scholes model, models with jumps.

This research was supported by the LMS grant R.STAA.3037 and through the program “Research in Pairs” by the Mathematisches Forschungsinstitut Oberwolfach in 2011. MU would like to thank the Statistics Department at Warwick, where a part of this work was carried out, for hospitality and a productive research atmosphere.
though there are many approaches to hedging in incomplete markets in the literature (see e.g. the papers Cont, Tankov and Voltchkova [5], Davis, Panas and Zariphopoulou [8], Denkl, Goy, Kallsen, Muhle-Karbe and Pauwels [11], Hubalek, Kallsen and Krawczyk [15], Schweizer [28], Tankov [32], the monographs Cont and Tankov [4], Delbaen and Schachermayer [10], Föllmer and Schied [12], Karatzas and Shreve [20], Shiryaev [29] and the references therein), which are applicable in rather general situations, the delta-hedging strategy remains the key tool in practice because it (1) affords a “natural” interpretation based on the BMS model and (2) typically possesses a computationally accessible implementation (one is required to work with functions of time and spot price rather than with general predictable processes on some stochastic basis). See, however, Taleb [31, Ch. 7], where some undesirable features of delta hedges in a practically oriented framework are pointed out.

Let \( V(t, x) \) be the time-\( t \)-value (with the stock price at level \( x \)) of a self-financing strategy that replicates some European contingent claim in the BMS model. The delta-hedging strategy is determined uniquely by the requirement that at each time \( t \) a trader following this strategy holds \( \frac{\partial V}{\partial x}(t, S_t) \) units of the stock (and the rest of the wealth in a riskless security), where \( S_t \) denotes the stock price at time \( t \). Put differently, the number of units of the stock to be held at time \( t \) is computed as a function of \( S_t \) by evaluating the partial derivative \( \frac{\partial V}{\partial x} \) of the value function.

To form an analogous strategy in a model other than BMS, where the stock price process \((S_t)_{t \in [0, T]}\) is càdlàg, we first need to understand what the function \( V(t, x) \) should be, since perfect replication is in general no longer possible. In the financial markets typically a pricing measure \( P \) is chosen from a possibly infinite class of equivalent local martingale measures. The value of a contingent claim is then assumed to be given by the conditional expectation of the claim’s payoff under the measure \( P \). Let \((\mathcal{F}_t)_{t \in [0, T]}\) denote the filtration that models the market information. If \((S_t)\) is an \((\mathcal{F}_t, P)\)-Markov process, then the time-\( t \)-value of a contingent claim \( f(S_T) \) is therefore given by the function \( V(t, x) \), defined by the formula \( V(t, S_t) = \mathbb{E}_P(f(S_T)|\mathcal{F}_t) \). The key difference with the BMS model is that, due to the incompleteness of \((S_t)\), in general \( V(t, S_t) \) no longer represents the value of a replicating strategy. Nevertheless one can still define the delta-hedging strategy as the self-financing strategy that starts with the initial capital \( V(0, S_0) \) and holds \( \frac{\partial V}{\partial x}(t, S_t-) \) units of the stock at each time \( t \) (the argument \( S_t- \) is necessary to get a predictable strategy). In general the partial derivative of the value function \( \frac{\partial V}{\partial x} \) may not exist. However, since the delta-hedging strategy is widely used in the financial markets, it is necessary to understand its theoretical properties whenever it is well-defined.

The reason why the delta-hedging strategy works in the BMS model is based on the following two arguments:

(A) integral representation of Brownian martingales implies that any contingent claim is replicable;
(B) Ito’s formula for continuous semimartingales implies that the replicating strategy should necessarily take the form \( \frac{\partial V}{\partial x}(t, S_t) \).
For general càdlàg semimartingales Ito’s formula has a different form and even if the statement analogous to (A) were true, there would still be no justification for (B), i.e. in models with jumps there is no reason for the delta-hedging strategy to reduce, let alone eliminate, the remaining risk of a contingent claim. This point concerning (B) is generally disregarded in practice because in typical models with jumps the analogue of (A) fails to hold. The reasons why delta hedging is used in models with jumps can be summarized as follows:

(a) models with jumps applied in financial markets are incomplete and hence exact replication cannot be required from any hedging strategy;

(b) delta-hedging strategy appears quite naturally because it works in the BMS model, while the lack of its theoretical justification for models with jumps is attributed to (a) alone rather than to the inherent deficiencies of the strategy itself.

In this paper we consider a simple complete model with jumps and demonstrate that the delta-hedging strategy does not typically replicate claims that can be replicated by other strategies. This suggests that (a) should not be used to justify the shortcomings of the delta-hedging strategy in general and that alternative hedging strategies should also be pursued in practice.

The rest of the paper is organised as follows. Section 2 describes trading strategies and contingent claims in a general semimartingale model for the stock price. In Section 3 we define the aforementioned complete market with jumps and prove that the delta-hedging strategy fails to replicate contingent claims. We show that even in such a simple market model with jumps, an admissible strategy which replicates a given attainable contingent claim is not unique. For a general European payoff, we give an explicit formula for the admissible replication strategy starting from the minimal possible initial capital. In the case of a smooth payoff (which makes the delta-hedging strategy well-defined), we compare the value process of this strategy with that of the delta-hedging strategy.

2. TERMINOLOGY AND NOTATION

Given a semimartingale \( X \), we will use the notation \( \Delta X_t := X_t - X_{t-} \) and the convention \( X_{0-} := X_0 \), i.e. \( \Delta X_0 = 0 \).

Let a discounted stock price be modelled by a positive local martingale \( S = (S_t)_{t \in [0,T]} \) on a filtered probability space \( (\Omega, \mathcal{F}, (\mathcal{F}_t)_{t \in [0,T]}, P) \) (i.e. we start from the outset with a risk-neutral measure \( P \)). A strategy is a pair \( \pi = (x_0, \varphi) \), where \( x_0 \in \mathbb{R} \) and \( \varphi = (\varphi_t)_{t \in [0,T]} \) is a predictable \( S \)-integrable process. Here \( x_0 \) is interpreted as the initial capital of this strategy, and \( \varphi_t \) as the number of stocks that a trader following the strategy \( \pi \) holds at time \( t \). A discounted value process of a strategy \( \pi = (x_0, \varphi) \) is \( V_t^\pi = x_0 + \int_0^t \varphi_u \, dS_u, \ t \in [0,T] \). A strategy \( \pi = (x_0, \varphi) \) is admissible if its discounted value process is bounded from below, i.e. if it holds

\[
\int_0^t \varphi_u \, dS_u \geq -c \quad P\text{-a.s.,} \quad t \in [0,T],
\]
for some constant $c < \infty$. Admissibility condition (2.1) is needed in continuous time finance to preclude arbitrage via (practically unfeasible) strategies that achieve positive terminal cashflows by allowing unbounded losses in the meantime (see e.g. [9], [10], [14], or [29]). In this paper we define a contingent claim to be a random variable $f(S_T)$ for some Borel function $f : (0, \infty) \rightarrow \mathbb{R}$ such that

$$f(S_T) \geq -c \quad \text{P-a.s.}$$

for some constant $c < \infty$. Here $f(S_T)$ is interpreted as a discounted payoff at time $T$. A strategy $\pi = (x_0, \varphi)$ replicates a contingent claim $f(S_T)$ if $V^\pi_T = f(S_T)$ P-a.s. Note that if $f(S_T)$ is a contingent claim with $\mathbb{E} f(S_T) = \infty$ (the expectation is well-defined by (2.2)), then it cannot be replicated by an admissible strategy. Indeed, the discounted value process $V^\pi$ of an admissible strategy $\pi$ is a supermartingale (as a bounded from below local martingale) and hence $V^\pi_T \in L^1$, which implies that the P-a.s.-equality $V^\pi_T = f(S_T)$ cannot hold. In the rest of the paper we therefore consider contingent claims $f(S_T)$ with

$$\mathbb{E} f(S_T) < \infty$$

(in particular, $f(S_T) \in L^1$).

Random variables that do not satisfy (2.2) are not called contingent claims in this paper because we are only interested in contingent claims that can be replicated by admissible strategies. Likewise, we do not consider path-dependent claims here because, in order to speak about delta-hedging strategies, we only investigate contingent claims that are replicable by strategies with discounted value processes of the form $V(t, x)$ for some function $V(t, x)$, $t \in [0, T]$, $x \in (0, \infty)$.

### 3. Hedging in a Complete Market with Jumps

Let us consider a standard Poisson process $N = (N_t)_{t \in [0, T]}$, $0 < T < \infty$, starting from 0 with an intensity $\lambda > 0$ on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$, and let $(\mathcal{F}_t)_{t \in [0, T]}$ be the right-continuous filtration generated by $N$, i.e. $\mathcal{F}_t = \bigcap_{\varepsilon > 0} \sigma(N_u; u \in [0, t + \varepsilon])$. We set $X_t = N_t - \lambda t$, so $X$ is a martingale. Let us fix $S_0 > 0$, $\sigma > 0$ and consider the discounted stock price $(S_t)_{t \in [0, T]}$ driven by the SDE

$$dS_t = \sigma S_t \, dX_t, \quad \text{i.e.} \quad S_t = S_0 e^{\alpha N_t - \beta t}$$

with

$$\alpha = \log(1 + \sigma) > 0, \quad \beta = \sigma \lambda > 0.$$ 

In particular, $S$ is a strictly positive $(\mathcal{F}_t, \mathbb{P})$-martingale. It follows from [17, Th. II.4.5] and the fact that $(\mathcal{F}_t)$ is generated by $N$ that if $X$ (or equivalently, $S$) is an $(\mathcal{F}_t, \mathbb{Q})$-local martingale under some $\mathbb{Q} \sim \mathbb{P}$, then $\mathbb{Q} = \mathbb{P}$ (i.e. $\mathbb{P}$ is the unique equivalent risk-neutral measure).
In order to replicate a contingent claim \( f(S_T) \) satisfying \((2.2)\) and \((2.3)\) let us define the \((\mathcal{F}_t)\)-martingale
\[
U_t = \mathbb{E}(f(S_T)|\mathcal{F}_t), \quad t \in [0,T].
\]
In particular, \( U_0 = \mathbb{E}f(S_T) \). By \cite{17} Th. III.4.37, there is a predictable process \( \tilde{\varphi} \) with \footnote{As in \cite{17}, we denote by \( A^+_{\text{loc}} \) the class of nondecreasing adapted càdlàg processes \( A \) with \( A_0 = 0 \) such that there exists a nondecreasing sequence of stopping times \( (\tau_n) \) with \( \tau_n = T \) \( \pound \Omega \) \( \mathbb{P} \)-a.s. and \( \mathbb{E}A_{\tau_n} < \infty \).} \( \int_0^T |\tilde{\varphi}_u| \, dN_u \in A^+_{\text{loc}} \) (or equivalently, \( \int_0^T |\tilde{\varphi}_u| \, du < \infty \) \( \mathbb{P} \)-a.s.) such that
\[
U_t = U_0 + \int_0^t \tilde{\varphi}_u \, dX_u, \quad t \in [0,T],
\]
and hence
\[
U_t = U_0 + \int_0^t \varphi_u \, dS_u, \quad t \in [0,T],
\]
where \( \varphi_u := \frac{\tilde{\varphi}_u}{\sigma S_u} \). Thus, \( \pi := (U_0, \varphi) \) is an admissible strategy replicating \( f(S_T) \). Furthermore, we have \( U_t = V_t^\pi, \ t \in [0,T] \).

This simple model based on the Poisson process is similar to the BMS model in the following way: a contingent claim can be replicated from any initial capital via a possibly non-admissible strategy \( U \) constructed in \((3.3)\) and \((3.4)\) we have \( \pi \) is an admissible strategy replicating \( f(S_T) \). Furthermore, we have \( U_t = V_t^\pi, \ t \in [0,T] \).

**Proposition 3.1.** Let \( f(S_T) \) satisfy \((2.2)\) and \((2.3)\).

(i) If \( \pi = (x_0, \varphi) \) is an admissible strategy replicating \( f(S_T) \), then \( x_0 \geq \mathbb{E}f(S_T) \).

(ii) For any \( x_0 \geq \mathbb{E}f(S_T) \), there exists an admissible strategy \( \pi = (x_0, \varphi) \) replicating \( f(S_T) \).

(iii) For any \( x_0 < \mathbb{E}f(S_T) \), there exists a non-admissible strategy \( \pi = (x_0, \varphi) \) replicating \( f(S_T) \).

**Proof.** (i) Let \( \pi = (x_0, \varphi) \) be an admissible strategy replicating \( f(S_T) \). Then \( V_t^\pi \) is a supermartingale as a local martingale bounded from below. Hence, \( x_0 \geq \mathbb{E}V_T^\pi = \mathbb{E}f(S_T) \).

(ii) For the admissible replicating strategy \( \pi = (U_0, \varphi) \) with the discounted value process \( U \) constructed in \((3.3)\) and \((3.4)\) we have \( U_0 = \mathbb{E}f(S_T) \). Now let \( x_0 > U_0 \) and set \( x = x_0 - U_0 \). If we construct a predictable process \( \tilde{\psi} \) with \( \int_0^T |\tilde{\psi}_u| \, du < \infty \) \( \mathbb{P} \)-a.s. such that \( M \), given by
\[
M_t := x + \int_0^t \tilde{\psi}_u \, dX_u, \quad t \in [0,T],
\]
is a nonnegative local martingale and \( M_T = 0 \) \( \mathbb{P} \)-a.s., then the strategy \( (x_0, \varphi + \psi) \), with \( \psi_u := \frac{\tilde{\psi}_u}{\sigma S_u} \), is admissible and replicates \( f(S_T) \).

To conclude the proof of this part of the proposition, we need to construct the process \( \tilde{\psi} \). For \( n \in \mathbb{N} \) let us set \( \tau_n = T \wedge \inf \{ t \in [0,T]: N_t = n \} \) (with \( \inf \emptyset := \infty \)). We define
\[
\tilde{\psi}_t = I_{\{0 \leq t \leq \tau_1\}} \frac{x}{\lambda T} + \sum_{n=1}^\infty I_{\{\tau_{n-1} < t \leq \tau_n\}} \frac{x}{\lambda T} \prod_{j=1}^n \left( 1 + \frac{1}{\lambda(T - \tau_j)} \right), \quad t \in [0,T].
\]
Then $\tilde{\psi}$ is a finite piecewise constant predictable process on $[0,T]$, hence $\int_0^T |\tilde{\psi}_u| \, du < \infty$ $\mathbb{P}$-a.s. A straightforward computation implies that the local martingale $M$ starting from $x$ defined in (3.5) via $\tilde{\psi}$ from (3.6) is nonnegative and we have $M_T = 0$ $\mathbb{P}$-a.s. This construction is illustrated in Figure 1.

(iii) For any $x > 0$, let us define the strategy $\pi := (-x, \varphi)$, where $\varphi := \frac{-\tilde{\psi}}{S_t}$ with $\tilde{\psi}$ given by (3.6). We have $V_0^\pi = -x$ and $V_T^\pi = 0$ $\mathbb{P}$-a.s. Together with parts (ii) and (i) this implies the result. \hfill

Thus, any contingent claim $f(S_T)$ satisfying (2.2) and (2.3) can be replicated via different admissible strategies with different initial capitals, but the discounted value process $U$ of the strategy $\pi = (U_0, \varphi)$ constructed in (3.2)–(3.4) starts from the minimal possible initial capital $U_0 = E f(S_T)$.

Now we are going to express the processes $U$ and $\varphi$ through the stock price process $S$.

We have

$$U_t = \mathbb{E}(f(S_T) \mid \mathcal{F}_t) = \mathbb{E} \left( f \left( S_t e^{\alpha (N_T - N_t) - \beta (T - t)} \right) \mid \mathcal{F}_t \right) = V(t, S_t) \quad \mathbb{P}\text{-a.s.},$$

where

$$V(t, x) = \mathbb{E} f \left( x e^{\alpha (N_T - N_t) - \beta (T - t)} \right) = e^{-\lambda (T - t)} \sum_{k=0}^{\infty} f \left( x e^{\alpha k + \beta t - \beta T} \right) \frac{\lambda (T - t)^k}{k!}.$$ (3.7)

Let us note that the series in the right-hand side of (3.7) converges absolutely for $x$ belonging to the support of the distribution of $S_t$ because $f(S_T) \in L^1$ and hence $\mathbb{E}(|f(S_T)| \mid \mathcal{F}_t) < \infty$ $\mathbb{P}$-a.s. Even though, for a fixed $x$, the function $t \mapsto V(t, x)$ is not necessarily càdlàg (recall that $f$ is just a Borel function $(0, \infty) \to \mathbb{R}$ satisfying (2.2) and (2.3)), $\mathbb{P}$-a.s. it holds:

$$t \mapsto V(t, S_t) \quad \text{is càdlàg and} \quad \lim_{u \searrow t} V(u, S_u) = V(t, S_{t-}), \quad t \in (0, T].$$ (3.8)
Indeed, substituting $x$ with $S_t$ in (3.7) we get

$$V(t, S_t) = e^{-\lambda(T-t)} \sum_{k=0}^{\infty} f \left( \sum_{j=0}^{k} \alpha_j \right) \frac{(\lambda(T-t))^k}{k!}. \quad \text{(3.9)}$$

A similar formula for $V(t, S_{t-})$ holds with “$N_{t-}$” replacing “$N_t$”. Then (3.8) follows by noting that $\mathbb{P}$-a.s. the process $N$ is càdlàg and piecewise constant, and that $\mathbb{P}$-a.s. the series in the right-hand side of (3.9) converges uniformly in $t \in [0, T]$. The latter (technical) point is formally justified in Appendix B.

**Proposition 3.2.** A version of the second component $\varphi$ of the admissible strategy $\pi = (U_0, \varphi)$ replicating a contingent claim $f(S_T)$ from the minimal possible initial capital $U_0 = \mathbb{E} f(S_T)$ is given by the formula

$$\varphi_t = \frac{V(t, (1 + \sigma)S_{t-}) - V(t, S_{t-})}{\sigma S_{t-}}, \quad t \in [0, T]. \quad \text{(3.10)}$$

Any other version is a predictable process that is equal to the right-hand side of (3.10) $\mathbb{P} \times \mu_L$-a.e. on $\Omega \times [0, T]$, where $\mu_L$ denotes the Lebesgue measure.

**Remark 3.3.** As a consequence of this proposition we also get the following statement, which is of interest when we work with specific contingent claims $f(S_T)$ and corresponding functions $V(t, x)$ (cf. with the end of this section). The process

$$\int_0^\tau (V(u, (1 + \sigma)S_{u-}) - V(u, S_{u-})) \, dX_u, \quad \text{which is a priori only a local martingale, is in fact always a true martingale bounded from below because, by Proposition 3.2 it equals } U - U_0 \text{ with } U \text{ given by (3.2). Furthermore, it is a bounded martingale whenever the contingent claim } f(S_T) \text{ is bounded.} \quad \text{(3.11)}$$

**Proof.** Let $\varphi$ be a predictable process from (3.4). Set $\tilde{\varphi} = \sigma S_{\cdot -} \varphi$, i.e. $\tilde{\varphi}$ is a predictable process with $\int_0^T |\tilde{\varphi}_u| \, du < \infty$ $\mathbb{P}$-a.s. and (3.3) holds. Then $\mathbb{P}$-a.s. we have

$$V(t, S_t) - V(t, S_{t-}) = \Delta U_t = \tilde{\varphi}_t \Delta X_t, \quad t \in [0, T]. \quad \text{(3.12)}$$

Since $\mathbb{P}$-a.s. it holds: $\Delta X$ only takes values 0, 1 and, for $t \in [0, T]$, $S_t = e^{\varphi} S_{t-} = (1 + \sigma) S_{t-}$ when $\Delta X_t = 1$, then the process

$$\tilde{\psi}_t := V(t, (1 + \sigma)S_{t-}) - V(t, S_{t-}), \quad t \in [0, T],$$

is a natural candidate for the process $\tilde{\varphi}$. Indeed, by (3.3), $\tilde{\psi}$ is an adapted left-continuous process with finite right-hand limits, hence $\tilde{\psi}$ is predictable and locally bounded. Consequently, $\int_0^T |\tilde{\psi}_u| \, du < \infty$ $\mathbb{P}$-a.s. and the integral $\int_0^\tau \tilde{\psi}_u \, dX_u$ is well-defined. It remains to prove that $\mathbb{P} \times \mu_L(\tilde{\varphi} \neq \tilde{\psi}) = 0$.

Let us set $\tilde{\chi} = \tilde{\varphi} - \tilde{\psi}$ and $Y = \int_0^\tau \tilde{\chi}_u \, dX_u$. Since $\int_0^T |\tilde{\chi}_u| \, du < \infty$ $\mathbb{P}$-a.s., the local martingale $Y$ is the difference of the Lebesgue–Stieltjes integrals $\int_0^\tau \tilde{\chi}_u \, dN_u - \int_0^\tau \tilde{\chi}_u \lambda \, du$. As a local martingale
of finite variation $Y$ is a purely discontinuous local martingale (see \cite[Lem. I.4.14 b)]{17}). But $Y$ does not have jumps because both $\tilde{\varphi}$ and $\tilde{\psi}$ satisfy (3.12). Hence, by \cite[Th. I.4.18]{17}, $Y_t = 0$ $\mathbb{P}$-a.s., $t \in [0, T]$. We have

$$
(3.13) \quad \int_0^t \tilde{\chi}_u dN_u = \int_0^t \tilde{\chi}_u \lambda \, du \quad \mathbb{P}\text{-a.s.,} \quad t \in [0, T].
$$

Since in the left-hand side of (3.13) we have a pure jump process and in the right-hand side a continuous process, both of them vanish $\mathbb{P}$-a.s., and we get $\mathbb{P} \times \mu_L(\tilde{\chi} \neq 0) = 0$. This concludes the proof.

Proposition 3.3 implies that the admissible strategy $\pi = (U_0, \varphi)$ with the discounted value process $U$, given in (3.2) and (3.4), replicates the contingent claim $f(S_T)$ from the minimal possible initial capital $U_0 = \mathbb{E} f(S_T)$. Now we are going to compare the strategy $\pi$ with the delta-hedging strategy $\rho = (U_0, \delta)$, $\delta_t = \frac{\partial V}{\partial x}(t, S_t)$, and their respective discounted value processes $V^\pi$ and $V^\delta$. However, in order to make such a comparison, we need to assume additional regularity of the function $f$, because in general there is no reason for the value function $V$ in (3.7) to be differentiable in the space variable.

Let a Borel measurable function $f : (0, \infty) \to \mathbb{R}$ satisfy (2.2) and (2.3) and assume that the following two conditions hold:

$$
(3.14) \quad f \in C^1(0, \infty)
$$

and for every $x_0 \in (0, \infty)$ there exists $\varepsilon \in (0, x_0)$ such that

$$
(3.15) \quad \sum_{k=0}^{\infty} \left| f'(xe^{\alpha k}) \right| \frac{(e^{\alpha \lambda T})^k}{k!} \quad \text{converges uniformly for} \quad x \in (x_0 - \varepsilon, x_0 + \varepsilon).
$$

The parameter $\alpha$ in (3.15) is defined in (3.1) and $\lambda$ is the intensity of the Poisson process $N$. The following result will allow us to define the delta-hedging strategy (recall that $\beta$ is defined in (3.1)).

**Proposition 3.4.** Assume that a function $f : (0, \infty) \to \mathbb{R}$ satisfies (2.2), (2.3), (3.14) and (3.15). Then the partial derivative $\frac{\partial V}{\partial x}(t, x)$ of the function $V : [0, T] \times (0, \infty) \to \mathbb{R}$, defined in (3.7), exists and is, for any $(t, x) \in [0, T] \times (0, \infty)$, given by the formula

$$
\frac{\partial V}{\partial x}(t, x) = e^{-(\lambda + \beta)(T-t)} \sum_{k=0}^{\infty} f'(xe^{\alpha k + \beta t - \beta T}) \frac{(e^{\alpha \lambda (T-t)})^k}{k!}.
$$

Furthermore the function $\frac{\partial V}{\partial x} : [0, T] \times (0, \infty) \to \mathbb{R}$ is continuous.

In order to prove Proposition 3.4 we recall the following known lemma from analysis. Note that the sequence of functions $(F_n)_{n \in \mathbb{N}}$ below is only assumed to converge at a single point.

**Lemma 3.5.** Let $F_n \in C^1(0, \infty)$ for $n \in \mathbb{N}$ and assume $F_n(x_0) \to A \in \mathbb{R}$ for some $x_0 > 0$. If there exists $G : (0, \infty) \to \mathbb{R}$ such that the sequence $(F'_n)_{n \in \mathbb{N}}$ converges locally uniformly to $G$, then there exist $F \in C^1(0, \infty)$ such that $(F_n)_{n \in \mathbb{N}}$ converges locally uniformly to $F$ and $F' = G$. 

Proof of Proposition 3.4. Fix any \( t \in [0, T] \) and define a sequence of functions

\[
F_n(x) = e^{-\lambda(T-t)} \sum_{k=0}^{n} f \left( xe^{\alpha k + \beta t - \beta T} \right) \frac{(\lambda(T-t))^k}{k!}, \quad x \in (0, \infty), \; n \in \mathbb{N}.
\]

Since \( T - t \leq T \), condition (3.15) implies that the function \( G: (0, \infty) \to \mathbb{R} \), given by \( G(x) := \lim_{n \to \infty} F'_n(x) \), is well-defined and that the sequence \((F'_n)_{n \in \mathbb{N}}\) converges locally uniformly to \( G \) on the interval \((0, \infty)\). Assumptions (2.2) and (2.3) imply that \( f(S_T) \in L^1 \) and hence we find

\[
e^{-\lambda T} \sum_{k=0}^{\infty} \left| f \left( S_0 e^{\alpha k - \beta t} \right) \right| \frac{(\lambda T)^k}{k!} = E|f(S_T)| < \infty.
\]

This implies that for \( x_0 = e^{-\beta t} S_0 \in (0, \infty) \), the sequence \((F_n(x_0))_{n \in \mathbb{N}}\) converges to a real number. Lemma 3.5 now implies differentiability of \( V \) in \( x \) and the formula for \( \frac{\partial V}{\partial x}(t, x) \).

To prove the continuity of the function \( \frac{\partial V}{\partial x} \), pick any \((s_0, y_0) \in [0, T] \times (0, \infty) \). Let \( \varepsilon > 0 \) be as in (3.15) for \( x_0 := y_0 e^{\beta s_0 - \beta T} \). Then there exists \( \varepsilon' > 0 \) such that any \((s, y) \in B_{\varepsilon'}(s_0, y_0)\), where the ball is given by \( B_{\varepsilon'}(s_0, y_0) = \{(s', y') \in [0, T] \times (0, \infty) : \max\{|s' - s_0|, |y' - y_0|\} < \varepsilon'\} \), satisfies \(|x_0 - ye^{\beta s - \beta T}| < \varepsilon\). Assumption (3.15) and the fact \( T - s \leq T \) for all \((s, y) \in B_{\varepsilon'}(s_0, y_0)\) imply that the series

\[
\sum_{k=0}^{\infty} \left| f' \left( ye^{\alpha k + \beta s - \beta T} \right) \right| \frac{(\alpha \lambda(T-s))^k}{k!} \quad \text{converges uniformly in} \quad (s, y) \in B_{\varepsilon'}(s_0, y_0).
\]

This implies joint continuity of \( \frac{\partial V}{\partial x} \).

Under the assumptions of Proposition 3.4, we define the **delta-hedging strategy** for the contingent claim \( f(S_T) \) to be \( \rho = (U_0, \varphi) \) with \( U_0 = ES_T \) (cf. with Proposition 3.1) and

\[
(3.16) \quad \delta_t = \frac{\partial V}{\partial x}(t, S_t), \quad t \in [0, T].
\]

Let us note that \( \delta \) is \( S \)-integrable as an adapted left-continuous process with finite right-hand limits (hence predictable and locally bounded). Below we again use the notation \( \pi = (U_0, \varphi) \) for the admissible strategy replicating \( f(S_T) \) given in Proposition 3.2. It is clear from (3.10) and (3.16) that in general the strategies \( \rho \) and \( \pi \) have different discounted value processes and, in particular, the delta-hedging strategy \( \rho \) does not replicate \( f(S_T) \).

Let us set

\[
(3.17) \quad \tilde{\varphi}_t = \sigma S_t \varphi_t = V(t, (1 + \sigma)S_t) - V(t, S_t), \quad t \in [0, T],
\]

\[
(3.18) \quad \tilde{\delta}_t = \sigma S_t \delta_t = \sigma S_t \frac{\partial V}{\partial x}(t, S_t), \quad t \in [0, T],
\]
and note that \( V^\pi = U_0 + \int_0^1 \bar{\varphi}_u \, dX_u \), \( V^\rho = U_0 + \int_0^1 \bar{\delta}_u \, dX_u \). The discounted replication error of the delta-hedging strategy \( \rho \) is thus given by the formula

\[
V^\rho_T - f(S_T) = \int_0^T \left( \bar{\delta}_u - \bar{\varphi}_u \right) \, dX_u
\]

\[
= -\int_0^T \left( V(u, (1 + \sigma)S_{u-}) - V(u, S_{u-}) - \sigma S_{u-} \frac{\partial V}{\partial x}(u, S_{u-}) \right) \, dX_u.
\]

In particular, we have \( \mathbb{E}(V^\rho_T - f(S_T)) = 0 \) whenever \( V^\rho \) is a true martingale (note that \( V^\pi \) is always a true martingale by Remark 3.3). However, this fact cannot serve as a partial justification for using the delta-hedging strategy in models with jumps, because it holds only under the risk-neutral measure. Under a real-world probability measure the process \( X \) is typically not a local martingale, and hence the replication error of the delta-hedging strategy is typically biased (i.e. has a non-zero mean).

Finally, let us compare the strategies \( \pi \) and \( \rho \) in the following examples.

**Example 3.6.** Consider a contingent claim given by \( f(S_T) = \log S_T \). Note that the payoff \( \log S_T \) is of interest in practice as it arises naturally in the context of the derivatives on variance (see e.g. [13]). Clearly, the assumptions of Proposition 3.4 are satisfied (note that \( S_T \geq S_0 e^{-\beta T} > 0 \) \( \mathbb{P} \)-a.s.). By (3.7), \( V(t, x) = \log x + g(t) \) with some continuous function \( g \) (which can be computed explicitly). By (3.17) and (3.18), we have

\[
\bar{\varphi}_t \equiv \log(1 + \sigma), \quad \bar{\delta}_t \equiv \sigma, \quad t \in [0, T],
\]

hence

\[
V^\pi_t = U_0 + (\log(1 + \sigma)) X_t, \quad V^\rho_t = U_0 + \sigma X_t, \quad t \in [0, T].
\]

In particular, \( \pi \) and \( \rho \) are admissible, \( V^\pi \) and \( V^\rho \) are true martingales, \( \pi \) replicates \( \log S_T \), but \( \rho \), which is the delta-hedging strategy for \( \log S_T \), replicates an affine transformation of \( \log S_T \).

**Example 3.7.** Consider \( f(S_T) = S_T^a \) with some \( a \in \mathbb{R} \setminus \{0\} \). Again, the assumptions of Proposition 3.4 are satisfied. By (3.7), \( V(t, x) = x^a g(t) \) with some continuous function \( g \). We get

\[
\bar{\varphi}_t = \left( (1 + \sigma)^a - 1 \right) S_{t-}^a g(t), \quad \bar{\delta}_t = a \sigma S_{t-}^a g(t), \quad t \in [0, T].
\]

It follows that

\[
(3.19) \quad V^\rho - U_0 = \frac{a \sigma}{(1 + \sigma)^a - 1} (V^\pi - U_0).
\]

By Remark 3.3, \( V^\pi \) is a martingale bounded from below. Then, by (3.19), \( V^\rho \) is a martingale bounded from below (note that \( \frac{a \sigma}{(1 + \sigma)^a - 1} > 0 \) regardless of whether \( a > 0 \) or \( a < 0 \). In particular, the delta-hedging strategy \( \rho \) is admissible. But it does not replicate \( S_T^a \) if \( a \neq 1 \).

Finally, let us note that in the case \( a < 0 \) the payoff \( S_T^a \) is bounded. Hence by Remark 3.3 and the formula in (3.19) we have an example, where both discounted value processes \( V^\pi \) and \( V^\rho \) are bounded martingales, but the delta-hedging strategy does not replicate the contingent claim.
Appendix A.

In this section we briefly recall the notion of delta hedging in the BMS model. In particular, this will make precise the statements mentioned in the introduction such as which contingent claims can be replicated, whether Ito’s formula in (B) on page 2 can always be applied, etc. For general accounts of the BMS model in the literature on stochastic finance see e.g. the monographs [2], [3], [6], [16], [18], [19], [20], [23], [25], [29], [30], papers [1], [21] or the encyclopedia article [7].

Let us consider a standard Brownian motion \( W = (W_t)_{t \leq [0,T]}, \) \( 0 < T < \infty, \) starting from 0 on a probability space \((\Omega, \mathcal{F}, \mathbb{P})\), and let \((\mathcal{F}_t)_{t \in [0,T]}\) be the right-continuous filtration generated by \( W \). Let a discounted stock price be given by \( S_t = S_0 \exp\{\sigma W_t - (\sigma^2/2)t\} \) \( (S_0 > 0, \sigma > 0) \), i.e. we have \( dS_t = \sigma S_t dW_t \). In particular, \( \mathbb{P} \) is a risk-neutral measure, and if \( S \) is an \((\mathcal{F}_t, \mathbb{Q})\)-local martingale under some \( \mathbb{Q} \sim \mathbb{P} \), then \( \mathbb{Q} = \mathbb{P} \) (i.e. \( \mathbb{P} \) is the unique equivalent risk-neutral measure).

Let us now discuss how to replicate a contingent claim \( f(S_T) \) satisfying (2.2) and (2.3). Set
\[
U_t = \mathbb{E}(f(S_T)|\mathcal{F}_t), \quad t \in [0,T].
\]
Since \( U \) is an \((\mathcal{F}_t)\)-martingale and the filtration \( \mathcal{F}_t \) is generated by the Brownian motion \( W \), there exists a predictable process \( \tilde{\varphi} \) with \( \int_0^T \tilde{\varphi}_u^2 du < \infty \) \( \mathbb{P}\)-a.s. such that \( U_t = U_0 + \int_0^t \tilde{\varphi}_u dW_u, \) \( t \in [0,T] \), and hence
\[
U_t = U_0 + \int_0^t \varphi_u dS_u, \quad t \in [0,T],
\]
where \( \varphi_u := \frac{\tilde{\varphi}_u}{\sigma \varphi_u} \). In particular, the strategy \( \pi := (U_0, \varphi) \) replicates \( f(S_T) \), and \( V_t^{\pi} = U_t, \) \( t \in [0,T] \).
Finally, by (2.2) and (A.1), the process \( U(\equiv V^{\pi}) \) is bounded from below, hence \( \pi \) is admissible.

For completeness, we now state the analogue of Proposition 3.1 in the BMS model.

Proposition A.1. Let \( f(S_T) \) satisfy (2.2) and (2.3).
(i) If \( \pi = (x_0, \varphi) \) is an admissible strategy replicating \( f(S_T) \), then \( x_0 \geq \mathbb{E}f(S_T) \).
(ii) For any \( x_0 \geq \mathbb{E}f(S_T) \), there is an admissible strategy \( \pi = (x_0, \varphi) \) replicating \( f(S_T) \).
(iii) For any \( x_0 < \mathbb{E}f(S_T) \), there is a non-admissible strategy \( \pi = (x_0, \varphi) \) replicating \( f(S_T) \).

Proof. The proof is similar to that of Proposition 3.1. An analogue of the nonnegative strict local martingale \( M \) of (3.5) with \( M_0 = x > 0 \) and \( M_T = 0 \) \( \mathbb{P}\)-a.s. can be constructed also in the BMS model. One can find such examples in [26] or, alternatively, consult [18] Sec. 1.6.3. \( \square \)

Thus, any contingent claim \( f(S_T) \) satisfying (2.2) and (2.3) can be replicated via different admissible strategies with different initial capitals, but the discounted value process \( U \) of the strategy \( \pi = (U_0, \varphi) \) constructed in (A.1) and (A.2) starts from the minimal possible initial capital. Now we are going to prove that this strategy \( \pi \) has to coincide with the delta-hedging strategy.

We have
\[
U_t = \mathbb{E}(f(S_T)|\mathcal{F}_t) = \mathbb{E}\left( f\left( S_t e^{\sigma(W_T-W_t)-\frac{\sigma^2}{2}(T-t)} \right) |\mathcal{F}_t \right) = V(t, S_t) \quad \mathbb{P}\text{-a.s.},
\]
where \( V(t, x) := \mathbb{E} f (e^{x \xi}), t \in [0, T], x \in (0, \infty), \) with \( \xi \sim N(-\sigma^2 (T - t)/2, \sigma^2 (T - t)) \). The last equality in (A.3) follows from the facts that \( S_t \) is \( \mathcal{F}_t \)-measurable and \( W_T - W_t \) is independent of \( \mathcal{F}_t \).

Let us set \( \tilde{f}(y) = f (e^y), y \in \mathbb{R}, \) and \( \nabla(t, y) = V(t, e^y), t \in [0, T], y \in \mathbb{R}. \) Then

\[
\nabla(t, y) = \mathbb{E} \tilde{f}(y + \xi) = \frac{1}{\sqrt{2 \pi (T - t) \sigma}} \int_{\mathbb{R}} \tilde{f}(z) e^{-\frac{(z - y + \sigma^2 (T - t)/2)^2}{2 \sigma^2 (T - t)}} dz.
\]

It follows that \( \nabla \in C^{1,2}([0, T) \times \mathbb{R}) \) and hence \( V \in C^{1,2}([0, T) \times (0, \infty)). \)

By Ito’s formula,

\[
U_t = V(t, S_t) = U_0 + \int_0^t \frac{\partial V}{\partial x}(u, S_u) \, dS_u + A_t, \quad t \in [0, T),
\]

where \( A \) is a continuous process of finite variation. The stochastic integrals with respect to \( S \) in (A.2) and (A.4) are continuous local martingales. Thus, \( A \equiv 0 \) and the replicating strategy \( \pi = (U_0, \varphi) \) is the delta-hedging strategy: \( \varphi_t = \frac{\partial V}{\partial x}(t, S_t), t \in [0, T) \) (note that the terminal value \( \varphi_T \) is, in fact, irrelevant).

**Remark A.2.** The argument above also explains that it is essentially Ito’s formula for continuous semimartingales that justifies delta hedging in the BMS model, hence there is no reason for delta hedging to be a sensible strategy in models with jumps.

**Appendix B.**

Here we prove that under the condition \( f(S_T) \in L^1 \) we have that, for \( \mathcal{P} \)-a.a. \( \omega, \) the series in the right-hand side of (3.9) converges uniformly in \( t \in [0, T]. \)

Let \( M \in (0, \infty) \) and \( a_k \geq 0, k = 0, 1, \ldots, \) be deterministic numbers such that

\[
\sum_{k=0}^{\infty} a_k \frac{M^k}{k!} < \infty.
\]

Let \( (N_x)_{x \in [0, M]} \) be a deterministic nondecreasing càdlàg function with \( N_0 = 0 \) that takes only integer values and such that \( \Delta N_x, x \in [0, M], \) can take only values 0 and 1. In other words, \( (N_x) \) is a typical path of a Poisson process. Further let us define deterministic numbers \( m = N_M \) and \( \tau_1 = M \wedge \inf \{ x \in [0, M]: N_x = 1 \} \) (with \( \inf \emptyset := \infty \)) and note that \( \tau_1 > 0. \)

**Lemma B.1.** The series

\[
\sum_{k=0}^{\infty} a_k \frac{x^k}{k!} + x^{\tau_1}
\]

converges uniformly in \( x \in [0, M]. \)

**Proof.** Let \( R \) denote the radius of convergence of the power series (in \( x \))

\[
\sum_{k=0}^{\infty} a_k \frac{x^k}{k!}.
\]
By (B.1), \( R \geq M \). The \( m \) power series corresponding to \( m \) derivatives of (B.3) are
\[
\sum_{k=0}^{\infty} a_{k+l} x^k \frac{x^k}{k!}, \quad l = 1, 2, \ldots, m,
\]
and they have the same radius of convergence \( R \geq M \). Then all \( m + 1 \) series in (B.3) and (B.4) converge uniformly in \( x \in [0, M - \varepsilon] \) with \( \varepsilon := \frac{\tau_1}{2} \), hence the series in (B.2) converges uniformly in \( x \in [0, M - \varepsilon] \). It remains to note that (B.2) converges uniformly also in \( x \in [M - \varepsilon, M] \) due to (B.1) and the fact that \( N_{M-x} = 0 \) for \( x \in [M - \varepsilon, M] \).

Now using the notation of Section 3, we set \( M = \lambda T \) and \( a_k = |f(S_0 e^{\alpha k - \beta T})|, \ k = 0, 1, \ldots \). The condition (B.1) amounts to \( f(S_T) \in L^1 \), which is satisfied. Applying Lemma B.1 pathwise we get the desired result.
